

## Calculating the inverse Hessian

Now that we have found the forward operators that separately balance amplitude and frequency content from  $\mathbf{m}_0$  to  $\mathbf{m}_1$ , where  $\mathbf{m}_1 \approx \mathbf{H}\mathbf{m}_0$ , we want to find what combination of  $\mathbf{A}$  and  $\mathbf{S}$  best approximates  $\mathbf{H}$ . Since  $\mathbf{H} = \mathbf{L}^T \mathbf{L}$  is symmetric, we want our approximation of  $\mathbf{H}$  to be as close to symmetric as possible. Therefore, we define  $\mathbf{H}$  as

$$\mathbf{H} \approx \mathbf{A}^{1/2} \mathbf{S} \mathbf{A}^{1/2}, \quad (5.9)$$

where  $\mathbf{A}$  is the operator that balances the amplitudes of  $\mathbf{m}_0$  with respect to  $\mathbf{m}_1$ , and  $\mathbf{S}$  is the operator that balances the local frequency content of  $\mathbf{m}_0$  with respect to  $\mathbf{m}_1$ , both defined previously. Applying the operations in this order allows the approximation of  $\mathbf{H}$  to be symmetric because both  $\mathbf{A}$  and  $\mathbf{S}$  are symmetric operations. Splitting up our approximation to the Hessian into two separate operators allows us to control how much of each operation and the order of each operation goes into correcting the image, and see how it affects the resulting image. Now that we have found the forward Hessian,  $\mathbf{H}$ , such that  $\mathbf{H}\mathbf{m}_0 \approx \mathbf{m}_1$  using data matching operators, we want to find the inverse of this operator,  $\mathbf{H}^{-1}$ , such that  $\hat{\mathbf{r}} \approx \mathbf{H}^{-1}\mathbf{m}_0$  provides us with the least-squares image. This is found as

$$\mathbf{H}^{-1} \approx (\mathbf{A}^{1/2} \mathbf{S} \mathbf{A}^{1/2})^{-1} = \mathbf{A}^{-1/2} \mathbf{S}^{-1} \mathbf{A}^{-1/2}. \quad (5.10)$$

Because the amplitude operators only contain diagonal terms, they are simple to invert. However,  $\mathbf{S}^{-1}$  is non-trivial to calculate since inverse smoothing can create physically unrealistic high-frequency data if inverted incorrectly without regularization.

Figure 5.4 shows transfer functions for a stationary forward and inverse triangle smoothing operator of a radius of 10 samples. In the forward case, triangle

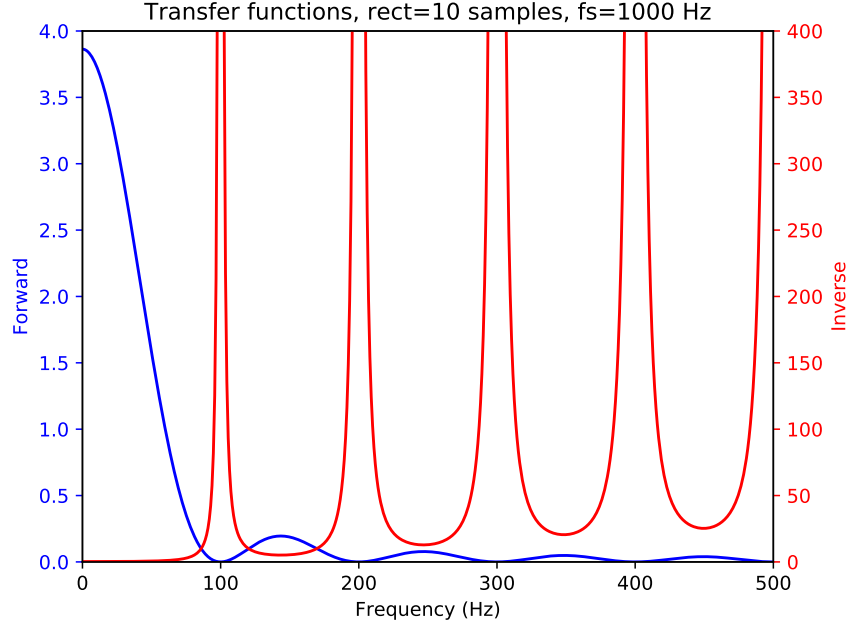

Figure 5.4: Transfer functions for a stationary forward triangle smoothing operator (blue) and its inverse (red). chapter-mighes/triop tf

smoothing acts as a low-pass filter. However, its inverse can introduce high frequency information, which is physically unrealistic for the data we are working with.

Therefore,  $\mathbf{S}^{-1}$  must be calculated with care to ensure the inverted data is physically plausible. We iteratively invert  $\mathbf{S}$  using shaping regularization (Fomel, 2007b), where the shaping operator is a bandpass filter picked to ensure the passband contains only physically possible frequencies for the given data set. The cost of applying our approximation to  $\mathbf{H}^{-1}$  in equation (5.10) is  $\mathcal{O}(N)$ , where  $N$  is the image size. The constant is small, typically around 10 for the number of iterations, and the calculation and application of this approximation is computationally insignificant compared to one iteration of least-squares migration.

## EXAMPLE

We demonstrate the effectiveness of this method on the 2D Sigsbee model. The Sigsbee2A 2D synthetic data set was created to mimic the geology of the Sigsbee escarpment in the Gulf of Mexico (Paffenholz et al., 2002). A fixed-spread acquisition survey is generated, which consists of 301 shots spaced every 122 m. The source wavelet for generating the synthetic data is a Ricker wavelet centered at 10 Hz. The record length of the synthetic data is 10 s with a sampling interval of 4 ms. We use reverse-time migration (RTM) as our migration operator.

Figure 5.5: The corrected migrated image, found by applying equation (5.10) to  $\mathbf{m}_0$ .  
[chapter-mighes/sigsbee migdec-shap](#)

We begin with the sub-surface reflectivity model (Figure 5.1(a)) and migration velocity model (Figure 5.1(b)). Next, we forward model the seismic data and migrate it to obtain our first conventionally migrated image,  $\mathbf{m}_0$  (Figure 5.2(a)). Then, we forward model  $\mathbf{m}_0$  and remigrate that data to obtain  $\mathbf{m}_1$  (Figure 5.2(b)). This pro-

vides us with the two images,  $\mathbf{m}_0$  and  $\mathbf{m}_1$ , that we can use to find the operation  $\mathbf{H}$  that maps  $\mathbf{m}_0$  to  $\mathbf{m}_1$ .

Next, we calculate and apply the data matching operations as described in the previous section. The forward amplitude balancing weight,  $\mathbf{A}$ , is shown in Figure 5.3(a). The calculated radius for the forward smoothing operation is shown in Figure 5.3(b). After applying these two operators to  $\mathbf{m}_0$  as described by equation (5.10), we produce the corrected migrated image, as shown in Figure 5.5. This corrected image better represents the subsurface reflectivity than the conventionally migrated image (Figure 5.2(a)), as it exhibits more correct amplitude content and higher resolution comparable with the reflectivity model.

Figure 5.6 shows a windowed section of the reflectivity model, the conventionally migrated image, and the corrected migrated image. The corrected migrated image exhibits clearly higher resolution and has more correct and consistent amplitude content than the conventionally migrated image.

In addition to directly applying this operator to the conventionally migrated image to improve resolution, this operator can be used as a preconditioner in iterative least-squares migration. In this case, the corrected migrated image could be used as an initial model for least-squares migration for faster convergence.

## CONCLUSIONS

Least-squares migration can produce an accurate migrated image, but it is more computationally expensive than conventional migration. In this chapter, we apply an approximate inverse Hessian operator to a conventional migrated image to approximate the least-squares migrated image. Because the primary differences between

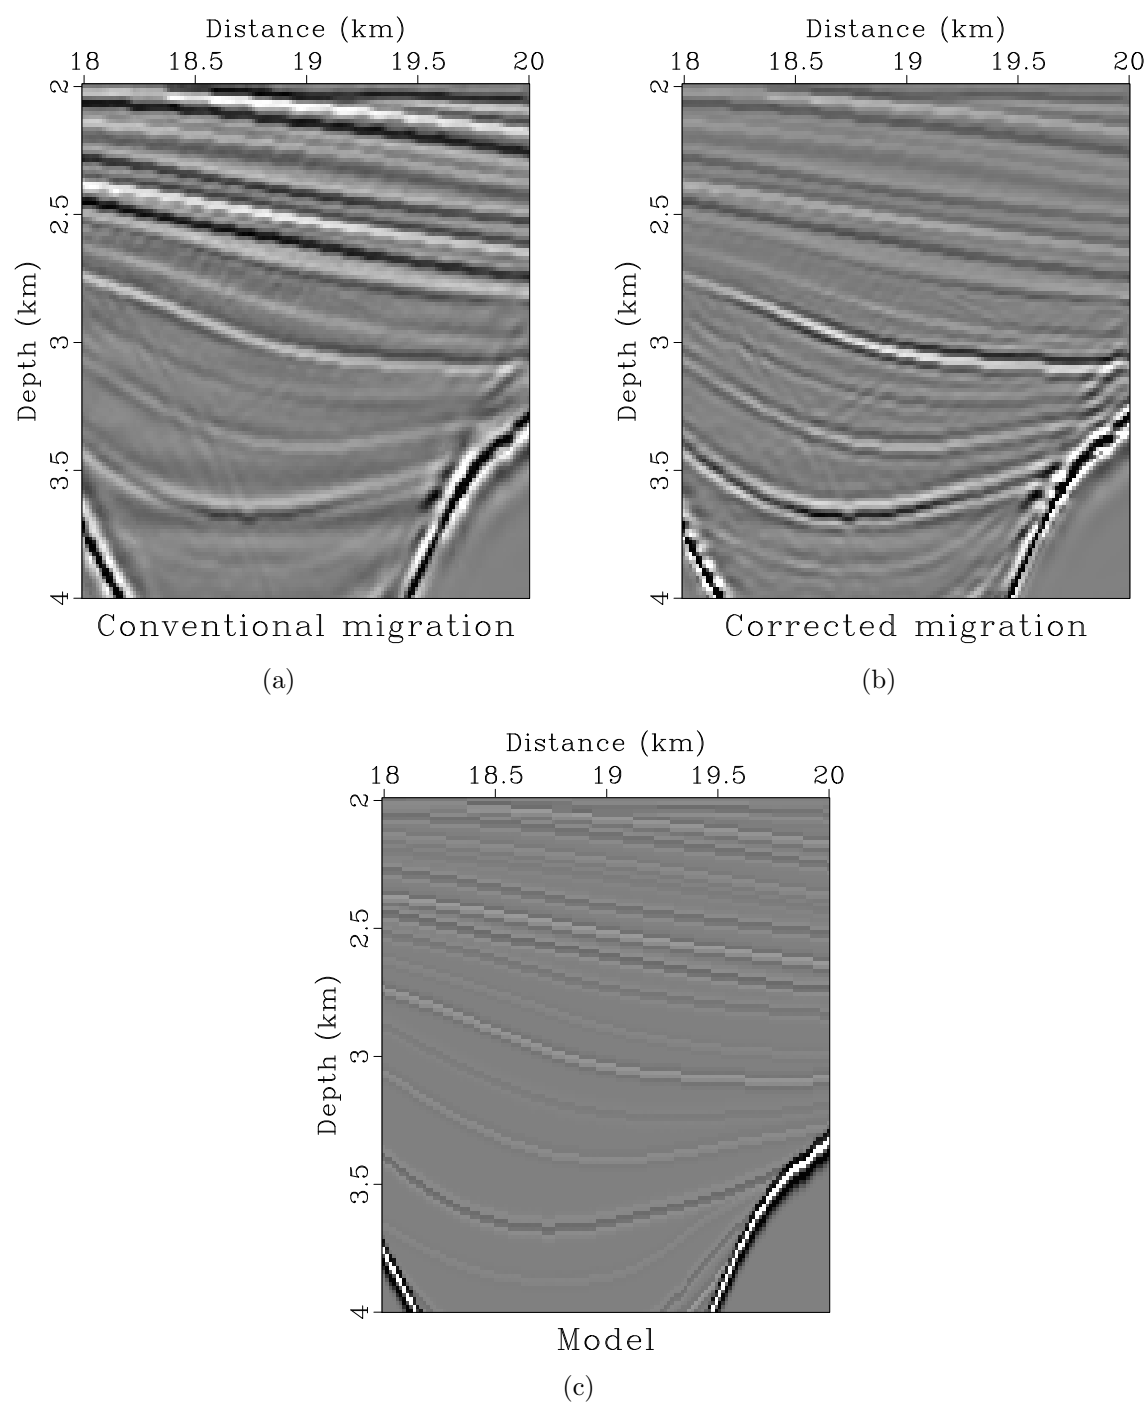

Figure 5.6: The first migrated image (a), the corrected migrated image (b), and the Sigsbee model reflectivity (c).  
 chapter-mighes/sigsbee image0-w3,migdec-w3,mod-w3

least-squares migration and conventional migration amount to amplitude and frequency variations, we approximate the forward Hessian by calculating frequency and amplitude matching operators. The amplitude matching operator is found by calculating the amplitude envelopes of migrated and remigrated images and smoothly dividing them, and the frequency matching operator is found using an iterative algorithm and non-stationary smoothing. The Hessian is approximated by a combination of these two operators to ensure symmetry. This method involves a windowless approach and is cheap to calculate and apply. Additionally, by defining the Hessian with two separate operators, we can examine, and control, the “ingredients” of the Hessian operator, and see how changing them impacts the final image.

After the forward Hessian is calculated, we invert it iteratively using shaping regularization, and apply it to the conventionally migrated image to get an approximation of the least-squares migrated image. Successful results are achieved on the 2D Sigsbee synthetic model with reverse-time migration as the migration operator.

## Chapter 6

### Conclusions

In this thesis, I discussed several methods and applications of data matching in seismic data analysis. Chapter 2 focuses on introducing the three data matching operators that are used in this thesis—shifting, scaling, and filtering. Chapter 3 introduces different methods of frequency balancing using non-stationary smoothing. The first method to find the non-stationary smoothing *radius*, or number of samples each data point is averaged over with a triangle weight, took a theoretical approach based off of the assumption that the data we observe can be modeled by a summation of Ricker wavelets. This method worked well in certain situations, but was not robust enough to work for any given data set. In the second method, I introduced an iterative algorithm to find the smoothing radius, and this method converges quickly and works well in several presented situations. Finally, a modification to this algorithm was shown and allows smoothing for more complex data sets.

This chapter also discusses two applications of these algorithms—the frequency balancing algorithm was demonstrated on an application of matching high-resolution and legacy seismic images, and the modified algorithm was demonstrated on an application of multicomponent seismic image registration.

Chapter 4 goes into more detail of the application of matching and merging high-resolution and legacy seismic images. This example takes two seismic volumes, acquired over the same area but using different technologies, and first matches them

before merging them together to produce an optimized third image. First, the method is demonstrated on a 2D line from the Gulf of Mexico. Then, the method is applied to a 3D seismic volume from a different part of the Gulf of Mexico.

Chapter 5 discusses another application of improving migration resolution by approximating the least-squares Hessian using non-stationary data matching operations. An approximation to the least-squares Hessian can be calculated by solving a data matching problem between two conventionally migrated images, and the Hessian can be represented by the combination of amplitude and frequency balancing operations. An example is applied to a 2D synthetic Sigsbee data set.

## **FUTURE WORK**

In the future, the work presented in Chapter 5 should be extended to involve real data and 3D examples. It also could benefit by comparing the results of the proposed approach taken in the chapter to other previous approaches presented to approximate the least-squares Hessian (Hu and Schuster, 1998; Dong et al., 2012; Casasanta et al., 2017; Dai and Schuster, 2013; Sacchi et al., 2007; Aoki and Schuster, 2009; Yu et al., 2006; Hu et al., 2001), to see how it compares in different situations.

Another extension of this data matching procedure may be to incorporate the phase of the signal to be matched. Negligible improvements were made when trying to incorporate phase corrections into the high-resolution and legacy data matching problem of Chapter 4, but other data matching problems could benefit from these corrections.

Several applications of data matching were discussed in this thesis. However, many applications remain unaddressed from a data matching standpoint. Problems

such as seismic and well-log tying, deconvolution, automatic gain control (AGC), and surface-related multiple elimination (SRME) can also be recast as data matching problems. Looking at these problems in a new light may bring advancements to computational geophysics.

## Appendix

## CODE

The examples in this thesis were implemented with the Madagascar open-source software environment for reproducible computational experiments (Fomel et al., 2013). The package is available at <http://www.ahay.org/>.

The reproducible document for the results in this thesis, including code, is available at <http://www.sygreer.com/research/honorsThesis>. However, some of the data used in this thesis are proprietary, so those results may not directly be reproducible.

For brevity in this thesis, code is only included for one example of the main frequency balancing algorithm presented in Chapter 3. The code for the rest of the examples in this thesis are available online at the URL above.

## Vita

Sarah graduated with high honors from Cinco Ranch High School in Katy, Texas in 2014 and came to The University of Texas at Austin to pursue her undergraduate studies. She is a candidate for a Bachelor of Science degree in Geophysics from the Jackson School of Geosciences and a Bachelor of Science degree in Mathematics from the College of Natural Sciences. After graduation, she plans on pursuing a PhD in Mathematics and Computational Science at the Massachusetts Institute of Technology.
